Abstract

We present an image quality metric based on the transformations associated with the early visual system: local luminance subtraction and local gain control. Images are decomposed using a Laplacian pyramid, which subtracts a local estimate of the mean luminance at multiple scales. Each pyramid coefficient is then divided by a local estimate of amplitude (weighted sum of absolute values of neighbors), where the weights are optimized for prediction of amplitude using (undistorted) images from a separate database. We define the quality of a distorted image, relative to its undistorted original, as the root mean squared error in this “normalized Laplacian” domain. We show that both luminance subtraction and amplitude division stages lead to significant reductions in redundancy relative to the original image pixels. We also show that the resulting quality metric provides a better account of human perceptual judgements than either MS-SSIM or a recently-published gain-control metric based on oriented filters.

Introduction

Many problems in image processing rely, at least implicitly, on a measure of image quality. Although mean squared error (MSE) is the standard choice, it is well known that it is not very well matched to the distortion perceived by human observers [1, 2, 3]. Objective measures of perceptual image quality attempt to correct this by incorporating known characteristics of human perception (see reviews [4, 5]). These measures typically operate by transforming the reference and distorted images and quantifying the error within that “perceptual” space. For instance, the seminal models described in [6, 7, 8] are based on psychophysical measurements of the dependence of contrast sensitivity on spatial frequency and contextual masking. Other models are designed to mimic physiological responses of neurons in the primary visual cortex. They typically include multi-scale oriented filtering followed by local gain control to normalize response amplitudes (e.g., [2, 9, 10]). Although the perceptual and physiological rationale for these models is compelling, they have complex parameterizations and are difficult to fit to data.

Some models have been shown to be well-matched to the statistical properties of natural images, consistent with theories of biological coding efficiency and redundancy reduction [11, 12]. In particular, application of Independent Component Analysis (ICA) [13] (which seeks a linear transformation that best eliminates statistical dependencies in responses), or sparse coding [14] (which seeks to encode images with a small subset of basis elements), yields oriented filters resembling V1 receptive fields. Local gain control, in a form known as “divisive normalization” that has been widely used to describe sensory neurons [15], has been shown to decrease the dependencies between filter responses at adjacent spatial positions, orientations, and scales [16, 17, 18, 19, 20].

A widely-used measure of perceptual distortion is the structural similarity metric (SSIM) [21], which is designed to be invariant to “nuisance” variables such as the local mean or local standard deviation, while retaining sensitivity to the remaining “structure” of the image. It is generally used within a multi-scale representation (MS-SSIM), allowing it to handle features of all sizes [22]. While SSIM is informed by the invariances of human perception, the form of its computation (a product of the correlations between mean-subtracted, variance-normalized, and structure terms) has no obvious mapping onto physiological or perceptual representation. Nevertheless, the computations that underlie the embedding of those invariances — subtraction of the local mean, and division by the local standard deviation — are reminiscent of the response properties of neurons in the retina and thalamus. In particular, responses of these cells are often modeled as bandpass filters (“center-surround”) whose responses are rectified and subject to gain control according to local luminance and contrast (e.g., [23]).

Here, we define a new quality metric, computed as the root mean squared error of an early visual representation based on center-surround filtering followed by local gain control. The filtering is performed at multiple scales, using the Laplacian pyramid [24]. While the model architecture and choice of operations are motivated by the physiology of the early visual system, we use a statistical criterion to select the local gain control parameters. Specifically, the weights used in computing the gain signal are chosen so as to minimize the conditional dependency of neighboring transformed coefficients. Despite the simplicity of this representation, we find that it provides an excellent account of human perceptual quality judgments, outperforming MS-SSIM, as well as V1-inspired models, in predicting the human data in the TID 2008 database [25].

Normalized Laplacian pyramid model

Our model is comprised of two stages (figure 1): first, the local mean is removed by subtracting a blurred version of the image, and then these values are normalized by an estimate of the local amplitude. The perceptual metric is defined as the root mean squared error of a distorted image compared to the original, measured in this transformed domain.

We view the local luminance subtraction and contrast normalization as a means of reducing redundancy in natural images.
Most of the redundant information in natural images is local, and can be captured with a Markov model. That is, the distribution of an image pixel \( x_i \) conditioned on all others is well approximated by the conditional

\[
p(x_i|\mathbf{x}_{Ni}) = \frac{1}{N_i} \sum_{j \in \mathcal{N}_i} |z_i - z_j| \tag{1}
\]

where \( \mathbf{x}_{Ni} \) is the vector of pixels in its immediate neighborhood. In each stage of the model, a parametric estimate of a statistic of the central pixel is gathered from its neighbors, and then removed; in the first stage, this statistic is the mean \( f_1 \):

\[
z_i = x_i - f_1(\mathbf{x}_{Ni}), \tag{2}
\]

and in the second stage, the amplitude \( f_2 \):

\[
y_i = z_i / f_2(z_{Ni}; \sigma, \mathbf{p}). \tag{3}
\]

Decomposition of an example image is shown in figure 2. All transformations in the model are translation invariant (i.e., the parameters of the two operations are identical for all locations). This considerably reduces the number of parameters of the model.

**Luminance subtraction stage**

We used the Laplacian pyramid [24] to implement luminance subtraction. This effectively decomposes the image using a multi-scale array of linear “difference of Gaussians” bandpass filters. At each scale, a lower resolution (blurred) version of the image is computed, and subtracted, implementing equation 2 (see fig. 1). The process is then applied recursively to the blurred (and downsampled) image. This linear stage has no free parameters, except for the number of scales, \( N \), which is chosen according to the resolution of the images (for examples in this paper, \( N = 6 \)).

**Contrast normalization stage**

As an estimate of the local amplitude of a coefficient at a given scale, \( k \), we use a linear combination of rectified neighbors:

\[
f_2(z_{Ni}; \sigma^{(k)}, \mathbf{p}^{(k)}) = \sigma^{(k)} + \sum_{j \in \mathcal{N}_i} p_j^{(k)} |z_j^{(k)}|, \tag{4}
\]

where \( \mathbf{p}^{(k)} \) is the vector of non-negative weights, and \( \sigma^{(k)} \) is a positive-valued constant, such that \( f_2 \) is guaranteed to be positive for all neighborhoods, avoiding division by zero. For each scale, the constant is set to the average of the absolute value:

\[
\sigma^{(k)} = \frac{1}{N_{i}^{(k)}} \sum_{j=1}^{N_{i}^{(k)}} |z_j^{(k)}|, \tag{5}
\]

where \( N_{i}^{(k)} \) is the number of coefficients in the subband at scale \( k \). The weight vector is chosen as the solution of the optimization problem:

\[
\mathbf{p}^{(k)} = \arg\min_{\mathbf{p}} \sum_{i=1}^{N_{i}^{(k)}} \left( |z_i^{(k)}| - f_2(z_{Ni}^{(k)}; \sigma^{(k)}, \mathbf{p}) \right)^2. \tag{6}
\]

Note that \( \sigma^{(k)} \) may be considered as an initial approximation for the absolute value of \( z \), and the weighted sum acts to adaptively tune this value. All parameters are optimized over a large set of (undistorted) images from the McGill natural image database [26]. This optimization was performed only on these undistorted images, with no access to information about the type of distortions nor perceptual data on which we subsequently tested the model.

**Distance metric**

Finally, our proposed perceptual metric is given by:

\[
D(x, \tilde{x}) = \frac{1}{N} \sum_{k=1}^{N} \frac{1}{\sqrt{N_{i}^{(k)}}} \|y^{(k)} - \tilde{y}^{(k)}\|_2, \tag{7}
\]

where \( y^{(k)} \) and \( \tilde{y}^{(k)} \) denote vectors containing the transformed reference and distorted image data, respectively. Note that we compute root mean squared error for each scale, and then average over these, effectively giving larger weight to the lower frequency coefficients (which are fewer in number, due to subsampling).

**Results**

To evaluate our model, we fit the gain control parameters (eq. 6) using the McGill image dataset [26] and then evaluated the resulting model in two different ways\(^1\). First, we examined

---

\(^1\) Code with the implementation of the proposed model and results on more image quality databases can be found at: http://www.cns.nyu.edu/~lcv/NLPyr
the ability of each stage of the normalized Laplacian transform to reduce redundant information between the central coefficient and its neighbors. Second, we compared the model distances to human perceptual responses over a large set of distorted images.

**Mutual information assessment**

Figure 3 illustrates the reduction of redundant information at each stage of the model. Each image shows the empirical pairwise mutual information [27] between a given coefficient (central pixel of each image) and each of its neighbors. Mutual information has been computed using one million samples from the reference images in the TID database [25]. The figure reports the results for the first scale – results for the other scales are similar. The information reduction from both stages of processing is seen to be quite substantial – a factor of roughly six and three, respectively.

**Image quality assessment**

In this experiment, we analyze how well our perceptual metric correlates with human reports of perceptual distortion. We have evaluated performance on grayscale-converted images from several different image quality databases. Due to space restrictions, we only show results for the TID2008 database [25] here (results for other databases are available online). This consists of 1700 different distorted images (17 different distortion types, at 4 different strengths, for each of 25 original images), each with its own mean opinion score (MOS; the mean rating of all participants who assessed a particular distorted image). For reference, we also show the results of measuring the RMSE between the reference and the distorted image in the image domain, as well as in the Laplacian pyramid domain. We compare the performance of our metric with the multi-scale version of the currently most widely used perceptual metric, MS-SSIM [22]. We also compare with a metric based on a V1-based model [10], which uses an oriented wavelet decomposition followed by divisive normalization. The parameters of this model were chosen based on a separate set of perceptual measurements.

Figure 4 shows DMOS (which is inversely proportional to the MOS) against the predictions of each of the quality metrics. We present three different numerical evaluations of the predictive ability of each metric. The first ($\rho_1$) is the Pearson correlation between each metric and the DMOS (correlations are, apart from the sign, identical for MOS and DMOS). To compute the second
and the third evaluations, we first fit generalized logistic functions with four parameters to the measurements (black line). Then, we compared this function with the DMOS for each image, in terms of the correlation ($\rho_2$) and the root mean squared error (RMSE).

As expected, of all metrics evaluated, the RMSE in the image domain provides the poorest predictions of human perception. This is a classical result and is the primary motivation for seeking better perceptual metrics [1, 2, 3]. MS-SSIM and the normalized V1 model perform comparably, with the V1 model exhibiting slightly better correlation ($\rho_1$), but MS-SSIM providing slightly better prediction error. The normalized Laplacian metric achieves notable improvements over both of these. Note that this is particularly surprising given that both the V1 model and MS-SSIM are optimized for perceptual performance, whereas the normalized Laplacian model parameters were optimized for redundancy reduction over an independent database of (undistorted) natural images. In addition, the logistic regression for the normalized Laplacian model (as well as the V1 model) is almost linear. Finally, note that most of the performance is derived from the non-linear normalization stage: the Laplacian pyramid alone offers only a modest improvement over RMSE in the image domain.

**Discussion**

We have presented a perceptual quality metric computed as the root mean squared error of images represented in a nonlinear multi-scale decomposition in which the local mean and amplitude have been removed, with parameters optimized to remove redundancy in natural images. We have shown that this representation accomplishes a significant reduction of redundancy, and transforms the data to a more perceptually relevant space. In particular, the model provides a better account of human perceptual quality judgements than either the widely-used MS-SSIM metric, or a biologically-inspired V1 model based on locally normalized responses of oriented filters. We expect this performance advantage could be further increased by choosing model parameters that optimize the fit to the human distortion ratings.

A number of previous image quality metrics have used local gain control [2, 9, 10], but all of them did so in the context of an oriented linear transform. Despite a large body of work that has been interpreted as evidence that oriented linear filters are an optimal choice for capturing statistical regularities in images [14, 28], several articles have shown that this optimum is shallow [29], that non-oriented linear filters are nearly as effective as oriented ones [30], and that local nonlinear gain control is a more effective means of reducing redundancy [31]. The comparisons of Fig. 4 suggest that the normalized non-oriented bandpass representation that we propose here may offer a better substrate for a quality metric than an oriented representation. This is admittedly a preliminary finding, and a more thorough comparison is needed. An interesting possibility is that a cascaded representation, in which the normalized Laplacian pyramid is followed by further decomposition into oriented subbands (and possibly another stage of local gain control), would be consistent with the cascaded physiology of the human visual system, and may prove an even stronger platform on which to build a quality metric.

It is worth emphasizing that the normalized Laplacian model parameters are optimized to minimize redundancies in the representation of undistorted natural images. Thus, although they embed no specific knowledge of the types of distortions on which the model is tested, they do capture important information about the statistical properties of natural images. This suggests that the model might also be useful as a platform for a no-reference image quality metric. Specifically, one could use a measure of mutual information (or another measure of statistical independence) of the normalized Laplacian representation of an image, to quantify its “naturalness” thus, the level of distortion), similar to the strategy followed in [32].

Finally, the TID database provides a useful, but limited, means of assessing the performance of a metric in matching human judgements. The set of distortions includes only those encountered in typical image processing settings, and the human responses are quite variable across observers. A more directed assessment can arise from examining artificial images, synthesized to maximize or minimize the distortions of one metric while holding constant another (MAD competition [33]). For example, images that maximize/minimize our metric while adhering to a fixed RMSE distortion in the pixel domain would provide a direct visualization of the types of error that the metric deems “worst” and “best”. Moreover, “adversarial” images generated with the normalized Laplacian metric while holding the MS-SSIM constant (or vice versa), would provide a direct visualization of how the two models differ, and thus an effective means of elucidating their relative advantages.

Figure 4. Comparison of quality metrics to human perceptual data. Each plot shows the inverse of the mean opinion score of human observers (DMOS) as a function of prediction of a quality metric, for 1700 images corrupted by different types and magnitudes of distortion (see key, top left). Performance of each metric is summarized with three numbers (provided above each plot): the Pearson correlation before fitting a logistic function ($\rho_1$), and the Pearson correlation ($\rho_2$) and the prediction error (RMSE) after fitting a logistic function (black line). First row right: root mean square error (RMSE) in the image domain. Second row left: MSE in a normalized oriented V1 model [10]. Second row right: multi-scale structural similarity index (MS-SSIM) [21]. Third row left: RMSE in the Laplacian pyramid domain. Third row right: RMSE in the normalized Laplacian domain (eq. 7).

Author Biography

Valero Laparra was born in València (Spain) in 1983, and received a B.Sc. degree in Telecommunications Engineering (2005), a B.Sc. degree in Electronics Engineering (2007), a B.Sc. degree in Mathematics (2010), and a PhD degree in Computer Science and Mathematics (2011). He is a postdoc in the Image Processing Laboratory (IPL) at Universitat de València, and currently a visiting postdoc in the Laboratory for Computer Vision at NYU, USA. More details in http://www.uv.es/lapeva/.

Johannes Ballé received his Dipl.-Ing. degree in Computer Engineering from RWTH Aachen University, Germany in 2007 and his Dr.-Ing. degree in Electrical Engineering (summa cum laude) from the same university in 2012, specializing in image and video compression. He is currently working as a postdoctoral fellow at New York University’s Center for Neural Science. His research interests include image statistics and processing, computational vision, information theory, as well as machine learning.

Alexander Berardino received his B.A. in Neuroscience with a concentration in computation and cognitive systems from Boston University in 2010. He subsequently spent 2 years as a research fellow in Biomedical Engineering at B.U. (2010-2012). He is currently pursuing his Ph.D. in Neural Science at New York University. His research interests lie at the intersection of image statistics and biological computation, as well as the analysis of mid-to-high level biological visual representations.

Eero P. Simoncelli (S’90–M’91–SM’04–F’09) received the B.Sc. degree summa cum laude in physics from Harvard University in 1984, studied applied mathematics at University of Cambridge for a year and a half, and received M.S. and Ph.D. degrees in electrical engineering from the Massachusetts Institute of Technology, in 1988 and 1993, respectively. He was an Assistant Professor of Computer and Information Science at the University of Pennsylvania from 1993 to 1996. In 1996, he moved to New York University, where he is currently a Professor in neural science, mathematics, and psychology. In 2000, he became an Investigator of the Howard Hughes Medical Institute under their new program in computational biology. His research interests span a wide range of topics in the representation and analysis of visual images, in both machine and biological systems.
